Abstract

The HFR-EU1 irradiation in the HFR Petten is performed in cooperation between the European FP5 project consortium HTR-F/F1 and the Institute of Nuclear Energy Technology (INET) of the Tsinghua University in Beijing, China.

The experiment consists in irradiating 3 German AVR pebbles and 2 INET pebbles to very high burn-up with fission gas release measurements. After irradiation, the pebbles will undergo post-irradiation examination and safety testing in the KÜFA facility at JRC.ITU.

This is the first progress report on this experiment combining the results of the first four irradiation cycles.

The irradiation had started on 30 September 2006.

This document contains the history of the irradiation including significant special events, nuclear data as well as temperature and fission gas release measurements.

Some preliminary attempts were made to analyze and interpret the information obtained so far.

Further reports will contain a summary of the irradiation, new neutronics predictions including fission gas birth rates and burn-up, as well as more detailed analysis of experimental results.

Further data is available to INET and the HTR-F/F1 partners on request.

Table of Contents

1	Irradiation History	5
1.1	Special events	5
1.2	Modifications of installation	6

1 Irradiation History

30.09.06 17:10 start cycle 06-08 1 scrams and 3 gas samples taken per capsule 29.10.06 09:00 end cycle 06-08
02.11.06 4:40 start cycle 06-09 2 scram and 3 gas samples taken per capsule 29.11.06 08:00 end cycle 06-09
2.12.06 18:40 start cycle 06-10 No scram and 3 gas samples taken per capsule 31.12.06 08:00 end cycle 06-10
3.01.07 06:40 start cycle 07-01 No scram but power perturbation from 14:20 to 17:10 on the 15th of January 3 gas samples taken per capsule 31.01.07 08:00 end cycle 07-01

1.1 Special events

After the first start of the experiment, it was initially foreseen to keep it for one week at the lowest possible temperature to remove humidity from the sample holder. A long scram (06.10.06 20:10 to 11.10.06 4:50) prolonged this situation until 16.10.06 12:30. Unlike HFR-EU1bis, for which initial temperatures (meaning temperatures while purging containments with pure Helium at BOI) were matching the target conditions, HFR-EU1 had much lower initial temperatures due to two phenomena:

- Steel emissivity was not implemented in the thermal calculation model,
- HFR conversion from HEU to LEU caused a local thermal flux decrease.

To reach nominal temperatures, significant Ne fractions had to be used quite early thus decreasing the margin for burn-up compensation that would be required later in the irradiation.

Due to the HFR buckling and the high position of the Chinese capsule, the expected initial fission power of the highest INET pebble was also decreased. Therefore, the temperatures of the INET pebbles were very different and could not both reach the target values. To compensate this situation, it was decided in agreement with INET to increase the nominal temperature of the lower INET pebble to 940°C (instead of 900°C).

1.2 Modifications of installation

After three reactor cycles, a significant burn-up was reached leading to fission power depletion that could not be compensated anymore by increasing the Ne fraction in the gas. Therefore, from the 4th cycle, the experiment moved from position H2 to H4 where the thermal flux is approx. 15% higher.

2 Nuclear Data

The information in this section is extracted from post-cycle nuclear calculations of the HFR core.

2.1 Fluxes, fluences and other data cycle 06-08

Table 11: Average temperatures and history of thermocouple behavior

In Table 11, the behavior of all 34 thermocouples was analyzed to obtain an idea about the reliability of the obtained data. The magenta lines indicate temperature measurements at pebble surfaces. Yellow boxes indicate suspicious behavior of the concerned thermocouple and thus potentially unreliable data.

Figure 17: Average temperatures in irradiation rig for all 4 irradiation cycles

Figure 18: Evolution of average temperatures during irradiation

In comparison with HFR-EU1Bis, thermocouples 1 to 14 rose with time to compensate the experiment wrong design (i.e. the HFR buckling leads to a lower fission rate for INET 1, which then required an increase of the initial capsule temperature set point from 900°C to 940°C).

Table 15: Time averaged temperature readings during cycle 07-01

7 Temperature Compensation

The experiment comprises 34 thermocouples connected in the rig-head to copper wires for data transmission to the temperature control unit and the data acquisition system of the HFR. These joints (Nisil/Nicrosil to copper wires) induce new thermocouples that might be influenced by temperature changes next to the plug and thus modify thermocouples values. As a matter of fact, three valves for capsule insulation are present in the rig-head close to the plug. They develop enough power to heat the thermocouple plug by approx. 30 K and could thus modify the readings. To avoid such systematic errors (that might vary with time depending on the use of the magnetic valves) four thermocouples were placed on the plugs to measure the real thermocouple signal deformations and thus deduce it from the readings.

Figure 70: Reference thermocouples for temperatures compensation cycle 07-01 (TC-HD-N1, TC-HD-N2, TC-HD-N3, TC-HDCH1, TC-HDCH2)

8 Fission Gas Release Measurements

In HFR-EU1 the fission gas release was measured according to the following procedure:

A continuous gas flow (50 ml/min) was maintained throughout the cycles and the He/Ne mixture was adjusted to attain the target temperatures of TC-9 and TC-19 as the reference thermocouples. The gas sampling procedure can be resumed to:

1. Check if the selected capsule temperature remained constant over a significant time (minimum one hour).
2. Isolate manually the selected capsule by closing GA-MV1 or GA-MV2 and GA-MV13 and switch the gas flow through the filter station by closing SP I.X-MV5 and opening SP I.X-MV6 to avoid perturbation in the capsule.
3. Read GA-Pt1, the reference temperature, the gas mixture content and the sampling time and note these data.
4. Manually remove the tank from the glove box and replace it by another one for the following gas sample.
5. Open GA-MV1 or GA-MV2, depending on which capsule will be sampled and GA-MV13, switch the flow of the capsule to be purged from the filter station to the gas analysis glove box and proceed to the gamma spectrometry of the sample taken.

8.1 Evaluation of R/B

A good indication of particle health is the fraction between fission gas release rate (R) and fission gas birth rate (B) as a function of accumulated burn-up. For this reason, the following formula out of [5] was investigated:

$$\ln \frac{R}{B} = \text{const1.} - n \ln \lambda$$

From the measured concentration of 3 Kr and 2 Xe isotopes (statistical error 4 - 10% for Kr-85m, Kr-87, Kr-88 and Xe-135 and up to 20% for Xe-133), the gas pressure and the He flow-rate, the release rate R can be determined.

The birth rate B is calculated using the nominal number of fissions on the date of sampling.

The burn-up is the one pre-calculated for the experiment. Later adjustments will be made once the analysis of the burn-up measurements of the pebbles, the gamma scan wires and the fluence detectors are available.

Due to the HEU/LEU conversion of the HFR and the move of the experiment to another position, the value B has to be recalculated (activity underway). These values will be communicated later. This prevents us at this point in time from presenting release over birth vs burn-up results. Figure 71 and Figure 72 display release vs. time for the two capsules.

Nevertheless, the quality of the R/B measurement (steady-state R/B) can still be evaluated.

Indeed, $\ln \frac{R}{B} = \ln \frac{R}{\text{fission_rate} * \text{yield}} = \ln \frac{R}{\text{yield}} - \ln \text{fission_rate}$ leading to:

$$\ln \frac{R}{\text{yield}} = \text{const2.} - n \ln \lambda$$

Considering $\ln R/\text{yield}$ instead of $\ln R/B$ for a fixed (even unknown) fission rate does not affect the plots inclination (characteristic of the measurement quality). For this reason, Figure 77 to Figure 84 display $\ln R/\text{yield}$ vs. $\ln \lambda_{\text{ef}}$ instead of $\ln R/B$ vs. $\ln \lambda_{\text{eff}}$. R.

Note the activity peaks in Figure 71 and Figure 72. These five measurements were made with the same sampling container which proved to be contaminated and which will not be used any longer. Figure 73 and Figure 74 present the same results, without measurement taken with this gab sample.

8.2 R/yield graph interpretation:

Concerning the INET pebbles, there is an acceptable fit between the Xe-135 measurement and the linear regression for Krypton isotopes. We can notice two exceptions: Measurement of 04/12/2006 and 08/01/2007 performed with the contaminated grab sample. Here, the measurements of Xe-135 are much higher than the expected position on the linear regression.

Concerning AVR pebbles, Xe-135 measurements cannot be fitted to the linear regression from the Krypton isotopes. In most cases, measurements are significantly lower than the expected position on the linear regression. Here again, we can notice three exceptions: Measurement of 21/11/2006, 13/12/2006 and 23/01/2007 where measurements of Xe-135 are much higher than the expected position on the linear regression. These were also performed with the contaminated grab sample.

To fit on the Kr linear regression, release over yield value for Xe-135 in the AVR case needs to be increased. This stresses that AVR pebbles retains better Xe-135 isotopes than INET ones.

8.3 Nal and Gamma spectrometry correlation

The Sweep Loop Facility was designed to perform online gas measurements. Therefore all first containment lines were foreseen with Nal scintillation detectors. These detectors were configured on the 196 keV peak of Kr-88 with the minimum bandwidth of 20 keV.

Figure 85 and Figure 86 display activity measurements performed with Nal and gamma spectrometry. Both figures underline the difficult correlation between both processes.

This can be partly explained by two phenomena:

- The values measured by the Nal detectors are still rather low. The detectors are placed in the HFR basement and were influenced by background noise. This is why the lead shielding of the instruments was improved.
- The selected peak being below 440 keV, Nal are sensitive to Ne-23 [7]. This could be evidenced by activity measurements of He/Ne mixtures from the 2nd containment which is irradiated but not in contact with the fuel. Increasing the total flow while keeping the mixture proportion led to an activity increase on the concerned Nal.

Figure 87 and Figure 88 evidence the latter phenomenon, leading to the conclusion that Nal detectors in the current configuration are of little use for gas release measurements.

This situation will be corrected for the next cycles by the following measures:

- test of multi-channel analysis with Nal detectors
- test of multi-channel analysis with HP Ge detectors

Figure 85: Nal and Gamma spectrometer measurements correlation for INET pebbles
